Riki Kobayashi

ACKNOWLEDGEMENTS

The author wishes to express his deep gratitude to the following persons and institutions:

Dr. Riki Kobayoshi for his continuous help and advice in all the phases of this work.

The members of the staff and the graduate students of the Chemical Engineering Department for their suggestions during this research and particularly to Mr. D. Gardner for his assistance in carrying out the computations.

Dr. John E. Parish, Foreign Student Adviser at The Rice Institute.

Mr. Sam Pollard for his assistance in the construction of the apparatus.

The Rice Institute for its hospitality and economic support through the Ora N. Arnold Fellowship.

Phillips Petroleum Co. and Tennessee Gas Transmission Co. for providing the light hydrocarbons and Petrotex Chemical Co. for the furfural donated.

OBJECTIVES OF RESEARCH

The objectives of this investigation were:

- a) To obtain experimental data in a chromatographic unit for several binary systems of light hydrocarbons (methane, ethane, ethylene, propane, butane) on n-dodecane, and derive from them vapor liquid equilibrium constants, (K values).
- b) To discuss some of the experimental factors that can affect the parameters which serves as the basis for calculating physical chemical data.
- c) To apply the principles of Gas-Liquid Partition Chromatography to determine activity coefficients at infinite dilution, and evaluate from them other thermodynamic data as free energy of solution, heat of solution, entropy of solution, etc., for a system used in extractive distillation. The systems studied were n-butane, the butenes, and butadiene 1,3 in furfural.

SUMMARY

A brief review of some important theoretical aspects of Gas-Liquid Partition Chromatography is presented, emphasizing in particular parameters connected with solution behavior.

Preliminary to measurements conducted on light hydrocarbon systems, an apparatus was built trying to insure the best possible conditions to obtain physical and thermodynamical data through chromatographic techniques. The apparatus is described in detail.

Experiments were performed with light hydrocarbons methane through normal butane as the solute and normal dodecane as the stationary phase, in a range of temperatures from 0 to 30°C, and pressures from 20 to 40 psia. The experimental equipment and technique were such that the concentration of the solute approached infinite dilution. Vapor-liquid equilibria ratios or K-values obtained from these experiments have been compared with values obtained from static tests. The agreement range from poor agreement in the case of methane to excellent agreement in the case of propane and n-butane.

The study of a system used in extractive distillation (n - butane, butenes, and butadiene 1,3 in furfural) is presented. Values for the activity coefficients at infinite dilution were obtained, which show inner consistency, and which are in substantial agreement with those reported by Mertes (28). This study covered a range of temperatures from -20 to 40°C and pressures from 20 to 40 psia.

The variation of the activity coefficients with temperature was used to evaluate the differential heats of solution of the hydrocarbons in furfural. Other related thermodynamic properties such as excess free energy of solution, relative volatilities, etc., were calculated and are reported.

INTRODUCTION

Partition chromatography is a technique in which the components of a mixture are distributed between two phases, one stationary supported on a solid bed of large area, and the other phase traveling through the stationary bed. When the moving phase is a gas the process is called: Gas-Liquid Partition Chromatography.

This technique has been widely used for analytical purposes. The possibility of extending its application was pointed out by Martin (24) who refers to gas chromatography "as a means, perhaps the easiest, for studying the thermodynamics of the interaction of a volatile solute with a non volatile solvent."

GLPC makes use of processes of solution and during recent years successful attempts have been made in using this technique to obtain physical chemical data relevant to the solution processes occurring in the column.

Porter et al (35) established the relation of the retention volumes obtained by GLPC with partition coefficients following the plate theory of Martin and Synge (23). They showed the agreement of this partition coefficients with those obtained from equilibrium measurements. Pierotti et al (33) discussed GLPC solvent effects in a quantitative empirical

manner giving attention to the activity coefficients and the structure of solutes and solvents at a given temperature.

Littlewood et al (22) introduced the corrected retention volume as a main chromatographic parameter and obtained heats of solution from the variation of retention volumes with temperature.

Anderson (16) established that corrected retention volume is satisfactory only if the heat of solution is required but if the entropy of solution is required also, the evaluation of partition coefficients is more satisfactory.

An expression relating the retention volume and activity coefficients, and a review of the foundations of some empirical relations connected with homologous series was discussed by Herington (14). A review of some theoretical aspects was made by Rock (38) who pointed out the relation of GLPC with extractive distillation. Rangel (36) used the expression obtained by Porter (33) to calculate partition coefficients and obtained some K values for methane and propane on n-decane.

The previous efforts have led to a better understanding of the GLPC as a means of obtaining thermodynamical data.

The close relation between partition chromatography and solution behavior have not yet been completely exploited however, and it is the purpose of this work to study vapor-liquid

equilibria of the light hydrocarbons and the non-ideality of solutions through their activity coefficients.

THEORY REVIEW

Gas-Liquid Partition Chromatography can be used to determine physical constants as well as for analytical purposes. In any case to achieve successful results good understanding of the theory is required. A brief review of the theory will be presented here.

Chromatography involves transport phenomena of several types: gas phase molecular and eddy diffusion, interphase mass transfer, liquid phase diffusion, etc. A complete description of the processes taking place lies beyond mathematical treatment at the present time. Simplifying assumptions have permitted the development of existing theories. Two major assumptions frequently made in theoretical treatments e.g. Van Deemter et al (40) are:

- a) That equilibrium concentrations between the two phases are proportional (Linear Chromatography).
- b) The exchange process between solute and the stationary liquid phase is thermodynamically reversible and immediately established. Furthermore, longitudinal diffusion and other processes having a similar effect are neglected. As will be seen later, for the case involved in this study (GLPC) the first assumption is valid, but not the second one.

When the condition dictated by assumption (a) obtains, two different approaches can be followed:

(1.) The "plate theory" that considers the chromatographic column in analogy to the distillation columns as consisting of a number of stages or plates, in each of which there is equilibrium between the two phases.

(2) The "rate theory" which considers the kinetic phenomena occurring in the column.

PLATE THEORY

Martin and Synge (23) were the first to exploit the similarity of the chromatographic technique with the process occurring in the distillation and extraction columns. The theory has been reviewed and extended by Mayer and Tompkins (25), Glueckauf (18) and others.

In this model, a packed column (in which equilibrium is not attained at any point) is visualized as a discontinuous medium divided into hypothetical finite segments each of which represents one effective theoretical plate. The height of that segment is called "height equivalent to a theoretical plate", or HETP. The HETP may be defined as a segment of packing along the direction of flow such that the mobile phase leaving it is in equilibrium with the mean concentration of solute in the stationary phase. Further assumptions introduced in order to make the equations manageable are:

a). The diffusion of solute from one plate to another is

negligible.

b). The HETP is small relative to the column length and remains constant throughout the column. (It has been shown (39) that this is true when the ratio of concentrations of the solute entering and leaving the plate is closed to one, that is, when the column has a large number of plates.)

c). At equilibrium, the distribution ratio of a solute between the two phases must be independent both of the absolute value of its concentration and of the presence of other solutes. This partition coefficient is assumed constant throughout the column.

d). The size of the sample and the method by which it is introduced into the column are such that the charge is initially contained in the first plate.

An isolated segment of column consists of a stationary liquid phase of volume V_s supported by a solid of volume V_o , leaving a void space V_m which is available for the flow of gases.

As a solute is eluted through the column, local dissolution of the solute in the stationary phase takes place. Let C_s be the concentration of the solute in the stationary phase and C_m be its concentration in the mobile phase. The ratio of the two concentrations, at the equilibrium, is called the partition coefficient H. This partition coefficient of a solute determines

the rate at which the concentration band of that solute travels down the column and hence determines the position of the elution curve of a solute with respect to the effluent volume.

Consider the advancement through the column of the elution curve of a particular solute in partition chromatography.

For a single theoretical plate, after solute breaks through from it, the following relation holds:

$$\begin{aligned} f C_o &= v_s C_s + v_m C_m = v C_m & (1) \\ \text{Feed} &= \text{Plate Content} = \text{Effluent} \end{aligned}$$

where:

v_s = volume of stationary phase in a theoretical plate.

v_m = volume of mobile phase in a theoretical plate.

f = feed volume.

C_o = concentration of solute in the feed.

v = effluent volume.

The first term represents the necessary amount of gas for accomplishing the elution process. The maximum concentration in the effluent would be equal to the concentration in the mobile phase, and the effluent volume in those conditions is termed "effective plate volume."

Rewriting (1) $C_m v_m + C_s v_s = v C_m.$

Dividing by C_m $v_m + v_s \frac{C_s}{C_m} = v$ (2)

This can be written $v_m + H v_s = v$

Where $H = \frac{C_s}{C_m}$ is called the partition or distribution coefficient. (3)

The partition chromatography in stages can be represented

Representation of General Stages in partition chromatography.

The material balance for the first plate (n=1) if a volume dM of the mobile phase flows through it is:

$$d(v_m C_m)_1 + d(v_s C_s)_1 = (C_0 - C_m) dM$$

$$(v_m dC_m)_1 + (v_s dC_s)_1 + C_{m1} dM = \begin{cases} C_0 dM & 0 \leq M \leq A \\ 0 & M > A \end{cases} \quad (4)$$

Where $M =$ Total Volume of the Mobile Phase flowed through

$A =$ Feed Volume = Volume of the Mobile Phase

while solute concentration > 0

$C_0 dM = 0 dM$ for $M > A$ means we are through feeding to first plate.

For any other plate:

$$(v_m dC_m)_n + (v_s dC_s)_n + C_{m_n} dM = (C_m)_{n-1} dM \quad n > 1 \quad (5)$$

Introducing (2) and (3) and with

$$\frac{(C_m)_n}{C_o} = y_n, \quad \frac{M}{V} = \omega \quad (6)$$

(4) and (5) give rise to the differential equations:

$$\frac{dy_1}{d\omega} + y_1 = \begin{cases} 1 & 0 \leq \omega \leq \frac{A}{V} \\ 0 & \omega > \frac{A}{V} \end{cases} \quad (7)$$

$$\frac{dy_n}{d\omega} + y_n = y_{n-1} \quad n > 1 \quad (8)$$

A boundary condition is given for the initial conditions,

for $M=0 \quad W=0 \quad Y_1 = Y_2 = \dots = Y_n = 0 \quad (9)$

The solution of (7) and (8) which are differences differential equations can be worked out for all the stages.

For the first stage with $0 \leq \omega \leq \frac{A}{V}$

$$\frac{dy_1}{d\omega} + y_1 = 1 \quad (10)$$

Linear differential equation of the type $\frac{dy}{d\omega} + Py = Q$

with general solution $y_1 e^{\int P d\omega} = \int Q e^{\int P d\omega} + C$

Substituting in (10) where $P = 1 \quad Q = 1$

$$y_1 e^{\omega} = e^{\omega} + C \quad (11)$$

applying boundary condition (9), $C_1 = -1$

Stage 1 $y_1 = 1 - e^{-\omega} \quad (12)$

For the second stage

$$y_2 e^w = \int (1 - e^{-w}) e^w dw + C_2$$

$$y_2 e^w = e^w - w + C_2 \quad \text{with bound. cond. (9) } C_2 = -1$$

$$\text{Stage II} \quad y_2 = 1 - (w+1) e^{-w} \quad (13)$$

For the third stage

$$y_3 e^w = \int [1 - (w+1) e^{-w}] e^w dw + C_3$$

$$y_3 e^w = e^w - \frac{w^2}{2} - w + C_3 \quad \text{with b.c. (9) } C_3 = -1$$

$$y_3 = 1 - \frac{w^2}{2} e^{-w} - w e^{-w} - e^{-w}$$

$$\text{Stage III} \quad y_3 = 1 - \frac{1}{2} (w^2 + 2w + 2) e^{-w} \quad (14)$$

For the stage n

$$y_n = \frac{1}{n-1!} \left[(w^{n-1} + (n-1)w^{n-2} + (n-1)(n-2)w^{n-3}) e^{-w} \right] \quad (15)$$

Consider the following integral:

$$\int_0^u u^{n-1} e^{-u} du = u^{n-1} e^{-u} + (n-1)u^{n-2} e^{-u} + (n-1)(n-2)u^{n-3} e^{-u} + \dots \quad (16)$$

It corresponds with the expression in brackets, and our expression for "y" can take the form:

$$\frac{1}{n-1!} \int_0^u u^{n-1} e^{-u} du$$

Let $u = w'$ where w' is a dummy variable. Our final expression for "y" becomes

$$y_n = \int_0^w e^{-w'} \frac{w'^{n-1}}{n-1!} dw' \quad \text{for } 0 \leq w \leq \frac{A}{V} \quad (17)$$

For the case $w > \frac{A}{V}$ The general solution corresponds to that treated before.

$$\frac{dy}{dw} + y_1 = 0$$

Stage I $y_1 = C_1 e^{-w}$ (18)

For the same column the expression (18) and (12) must be satisfied in the first plate to avoid discontinuity, then at $\frac{A}{V}$

$$1 - e^{-\frac{A}{V}} = C_1 e^{-\frac{A}{V}} \quad C_1 = e^{\frac{A}{V}} - 1$$

$$y_1 = (e^{\frac{A}{V}} - 1) e^{-w} \quad (19)$$

For the stage II

$$\frac{dy_2}{dw} + y_2 = (e^{\frac{A}{V}} - 1) e^{-w}$$

$$y_2 e^w = (e^{\frac{A}{V}} - 1) w + C_2 \quad (20)$$

At $w = \frac{A}{V}$ for continuity

$$y_2 = 1 - (w+1) e^{-w} = 1 - \left(\frac{A}{V} + 1\right) e^{-\frac{A}{V}}$$

$$\left[1 - \left(\frac{A}{V} + 1\right) e^{-\frac{A}{V}}\right] e^{\frac{A}{V}} = (e^{\frac{A}{V}} - 1) \frac{A}{V} + C_2$$

$$C_2 = e^{\frac{A}{V}} - \left(\frac{A}{V} + 1\right) - (e^{\frac{A}{V}} - 1) \frac{A}{V} = e^{\frac{A}{V}} \left(1 - \frac{A}{V}\right) - 1$$

$$y_2 = (e^{\frac{A}{V}} - 1) w e^{-w} + \left[e^{\frac{A}{V}} \left(1 - \frac{A}{V}\right) - 1\right] e^{-w}$$

$$y_2 = \left(we^{\frac{A}{V}} - w + e^{\frac{A}{V}} - \frac{A}{V} e^{\frac{A}{V}} - 1\right) e^{-w} \quad (21)$$

The expression in brackets corresponds as before to

$$\int_{w-\frac{A}{V}}^w u^{n-1} e^{-u} du$$

Let $u = w'$

Then

$$y_n = \int_{w-\frac{A}{V}}^w e^{-w'} \frac{w'^{n-1}}{n-1!} dw' \quad \text{for } w > \frac{A}{V} \quad (22)$$

But from (6)

$$y_n = \frac{C_{m_n}}{C_0}, \quad w = \frac{M}{V}$$

The equations (17) and (22) can then be written

$$C_{m_n} = \frac{C_0}{V} \int_0^M \frac{1}{n-1!} e^{-\frac{M'}{V}} \left(\frac{M'}{V}\right)^{n-1} dM', \quad 0 \leq M \leq A \quad (23)$$

$$C_{m_n} = \frac{C_0}{V} \int_{M-A}^M \frac{1}{n-1!} e^{-\frac{M'}{V}} \left(\frac{M'}{V}\right)^{n-1} dM' \quad \text{for } M > A \quad (24)$$

which express the shape and position of the moving band. The latter equation is particularly important because it represents the situation at the end of the column. The integrand of (24) is analogous to Poisson distribution function:

$$e^{-\mu x} = \frac{(\mu x)^r}{r!}$$

For large μx that means $\frac{M'}{V}$ in equation (24), (that would be a condition fulfilled at the end of the column if the number of plates is not too small), it can be approximated for a Gauss distribution function

$$\frac{1}{\sqrt{2\pi} \sigma} e^{-\frac{x^2}{2\sigma^2}}$$

Then

$$\frac{1}{(n-1)!} e^{-\frac{M'}{V}} \left(\frac{M'}{V}\right)^{n-1} \approx \frac{1}{\sqrt{2\pi} \frac{M'}{V}} \exp \left[-\frac{\left(\frac{M'}{V} - n\right)^2}{2 \left(\frac{M'}{V}\right)} \right] \quad (25)$$

This can be further approximated for large $\frac{M'}{V}$ as:

$$\frac{1}{\sqrt{2\pi n}} \exp - \left[\frac{\left(\frac{M'}{V} - n\right)^2}{2n} \right] \quad (26)$$

Introducing (26) for the integrand in equation (24), and replacing for a large number of plates $n - 1$ by n

$$C_{m_n} = \frac{C_0}{V \sqrt{2\pi n}} \int_{M-A}^M \exp \left[-\frac{\left(\frac{M'}{V} - n\right)^2}{2n} \right] dM \quad (27)$$

The concentration will reach a maximum when:

$$M = nV + \frac{1}{2} A.$$

For small feed volumes $A \ll M$ (27) becomes

$$(C_m)_n = \frac{A C_o}{\sqrt{2\pi n}} \exp \left\{ -\frac{\left(\frac{M'}{V} - n\right)^2}{2n} \right\} \quad (28)$$

The Retention Volume is defined as the volume of mobile phase passed into the column when C_m is a maximum, and is related to the column geometry and the partition coefficient for the solute in the same way as the effective plate volume is to the volume of mobile and stationary phase.

$$V_R = V_m + HV_s \quad (29)$$

then

$$V = \frac{V_R}{n}$$

Let $q_o = AC_o$ represent the amount of material charged in the column.

Substituting the relations in (28)

$$(C_m)_n = \frac{q_o}{\sqrt{2\pi n}} \frac{n}{V_R} \exp \left[-\left(\frac{1}{2n}\right) \left(\frac{M}{V} - n\right)^2 \right]$$

$$(C_m)_n = \frac{q_o}{\sqrt{2\pi n}} \frac{n}{V_R} \exp \left[-\left(\frac{1}{2n}\right) \left(\frac{Mn}{V_R} - n\right)^2 \right]$$

$$(C_m)_n = \frac{q_o}{\sqrt{2\pi n}} \frac{n}{V_R} \exp \left[-\left(\frac{n}{2}\right) \left(1 - \frac{M}{V_R}\right)^2 \right] \quad (30)$$

This equation gives the concentration of the solute in the effluent gas, C_m , as a function of the mobile gas passed into the column, M , the amount of material charged to the first plate, (q_0), the number of plates in the column, n , and the retention volume, V_R , equation (30) was obtained by Porter et al (35) from the earlier work of Martin and Synge (23).

Corrections. The retention volumes directly, or through other parameters derived from them, will be the basis for the estimation of certain physical constants. It is a necessary requirement, therefore, to apply several correction factors resulting from the choice of operating conditions and the experimental apparatus:

a). The pressure drop through the column.

The plate theory was originally developed for the case of liquid partition chromatography (23). James and Martin (17) extended it to the case of a gas in the mobile phase, provided a correction for the fact that the mobile phase is compressible and thus produces a gradient of gas velocity down the column.

The derivation of the equation was made with the assumption that the partial pressures of the substances to be separated are negligible with respect to that of the carrier gas.

The gas volume displaced per unit time is:

$$au = F \frac{P_0}{P} = K \frac{dp}{dx} \quad (31)$$

Where:

a = cross section of the column.

u = linear velocity of the gas at the point x

p = pressure of the gas at a point distant x from the outlet

P_0 = outlet pressure

F = Volumetric rate of flow at the outlet

K = constant for a given column.

Integrating

$$\frac{K}{P_0} \frac{p^2}{2} = Fx + C \quad (32)$$

At $x = 0$ $p = P_0$ and $K P_0 = C$

Then $K \frac{p^2}{P_0} = 2Fx + K P_0$

or:
$$K = \frac{2Fx P_0}{p^2 - P_0^2}$$

$$F = \frac{K(p^2 - P_0^2)}{2x P_0} = \frac{K P_0}{2x} \left[\left(\frac{p}{P_0} \right)^2 - 1 \right] \quad (33)$$

In a chromatographic column different solutes travel through it at different rates. The velocity of the solute relative to the velocity of the elution gas is given by the retardation

factor (10)

$$R_f = \frac{\text{movement of position of maximum concentration of solute}}{\text{movement of mobile phase in column over same time interval}}$$

The elution time is given by:

$$t = \int_0^l \frac{dx}{u R_f} \quad (34)$$

Introducing the value of u from the equation (31)

$$u = \frac{F P_0}{a P} \quad \text{and} \quad dx = \frac{K P dP}{F P_0}$$

Rewriting (34)

$$t = \int_{P_0}^{P_1} \frac{\frac{K P dP}{F P_0}}{\frac{F P_0 R_f}{a P}} = \int_{P_0}^{P_1} \frac{K P^2 a dP}{F^2 P_0^2 R_f} \quad (35)$$

R_f depends only on the nature of the gas, column characteristics, and temperature, but being a ratio of velocities should be independent of pressure because the different components will suffer the same velocity gradient.

Then

$$t = \frac{K a}{F^2 P_0^2 R_f} \int_{P_0}^{P_1} P^2 dP = \frac{K a}{F^2 P_0^2 R_f} \frac{P_1^3 - P_0^3}{3} \quad (36)$$

But

$$t F = V_R$$

$$V_R = \frac{K a P_0 \left[\left(\frac{P_1}{P_0} \right)^3 - 1 \right]}{3 F R_f} \quad (37)$$

Hence, with $x = l$, $\rho = \rho_i$ and Equation (33)

$$V_R = \frac{K a P_o \left[\left(\frac{P_i}{P_o} \right)^3 - 1 \right]}{\frac{3 K P_o R_f}{2l} \left[\left(\frac{P_i}{P_o} \right)^2 - 1 \right]}$$

$$V_R = \frac{2}{3} \frac{a l}{R_f} \frac{\left[\left(\frac{P_i}{P_o} \right)^3 - 1 \right]}{\left[\left(\frac{P_i}{P_o} \right)^2 - 1 \right]} \quad (38)$$

When P_i/P_o approaches to unity

$$\frac{\left[\left(\frac{P_i}{P_o} \right)^3 - 1 \right]}{\left[\left(\frac{P_i}{P_o} \right)^2 - 1 \right]} \longrightarrow \frac{2}{3} \quad (39)$$

Then

$$V_R = V_{R^o} = \frac{a l}{R_f} \quad (40)$$

where V_{R^o} = corrected retention volume for pressure drop.

Substituting (40) in (38)

$$V_{R^o} = V_R \frac{3}{2} \frac{\left[\left(\frac{P_i}{P_o} \right)^2 - 1 \right]}{\left[\left(\frac{P_i}{P_o} \right)^3 - 1 \right]} \quad (41)$$

This expression has been checked experimentally by James and Martin (17) and Littlewood (22).

(b) Correction for dead volume of apparatus.

The experimental retention time, previously mention represents the average time taken for a molecule of a gas to pass from the injection point to the thermal conductivity cell. This time is the sum of the time spent in the stationary phase and in the gas phase. As the interest lies in the gas-liquid

interaction, it is necessary to correct the retention time for the time spent for the flow of gas through the dead volume of the apparatus, specifically, the dead volume consists of the tube leading from the injection point of the sample to the column, and the tube leading from the column to the detector. The estimation involves the knowledge of these volumes as an apparatus constant and the flow rate of the gaseous phase.

c) Correction for Sample Volume.

The sample size charged to the chromatographic column may affect the apparent retention volume if charged over a significant period of time resulting in a band which spread over an appreciable length of column (35), (40). Porter (35) treated two cases: plug flow, and exponential mixing. Van Deemter (40) obtained the following development. The width of the elution curve was defined as the distance between the points of intersection of the tangents to the elution curve at the points of inflection, with the horizontal axis.

Introducing the dimensionless quantities:

$$m = \frac{M}{v\sqrt{n}} \quad , \quad a = \frac{A}{v\sqrt{n}} \quad (42)$$

equation (27) becomes

$$\frac{(C_m)_n}{C_o} = \frac{1}{\sqrt{2\pi}} \int_{m-a}^m e^{-\frac{1}{2}(m'-\sqrt{n})^2} dm' \quad (43)$$

From this equation and definition of error function

$$f(t) = \frac{2}{\sqrt{\pi}} \int_0^t e^{-y^2} dy$$

$$\frac{(C_m)_n}{C_o} = \text{erf} \frac{a}{2\sqrt{2}} \quad (44)$$

gives the dependence of the height $\frac{(C_m)_n}{C_o}$ to the parameter

$a = \frac{A}{v\sqrt{n}}$ Another expression was developed to show the de-

pendence of the width $\Delta m = \frac{\Delta M}{v\sqrt{n}}$ on \underline{a} . Plots of Δm vs \underline{a}

demonstrated (40) that for $a = \frac{A}{v\sqrt{n}} < .5$ or for

sample volumes $\leq \frac{.5^2 V_e}{v\sqrt{n}}$ (45)

the width Δm becomes almost independent of the feed volume.

d). Correction for Dead Volume of Detector.

The dead volume of the detector cell affects both retention volume and peak width. The effects are especially pronounced at high detector volumes and low retention volumes. The influence of this factor in the retention volumes must be considered when the highest accuracy is sought. This accuracy is inherently

necessary in the determination of retention volumes and partition coefficients from which physical constants are to be obtained.

Johnson and Stross (10) have developed the theory for detector corrections and used the theory to correlate experimental data reflecting detector dead volume. They assumed that the sample entered the detector exactly as it left the sample injector. Applying a material balance to the plug flow case, the rate of change of amount of sample in the detector with respect to the volume must equal the inflow to the detector minus the outflow:

$$\frac{dx}{dV'} = S - \frac{x}{Z} \quad (46)$$

where:

x = amount of sample in detector chamber, (g)

V' = volume of sample added to the column in plug flow, (c.c.)

S = concentration of sample entering detector (g/cc)

Z = detector volume (cc)

Applying the equation already derived for C_m (30), substituting in the material balance, equation (46)

$$\frac{dx}{dV} = \frac{q_0}{\sqrt{2\pi n}} \frac{n}{V_R} e^{\left[-\left(\frac{n}{2}\right)\left(1 - \frac{M}{V_R}\right)^2\right]} - \frac{x}{Z}$$

(47)

The general solution of this differential equation is given as

$$x = e^{-\frac{V}{Z}} \frac{q_0 n}{\sqrt{2\pi n} V_R} e^{\frac{n}{Z} \left(\frac{2V_R}{nZ} + \frac{V_R^2}{n^2 Z^2} \right)} \int -\frac{n}{2 V_R^2} \left[V - V_R \left(1 + \frac{V_R}{nZ} \right) \right]^2 dV + c'' e^{-\frac{V}{Z}} \quad (48)$$

In order to simplify, the parameter

$$t = \frac{V - V_R \left(1 + \frac{V_R}{nZ} \right)}{V_R / \sqrt{n}} \quad (49)$$

is introduced.

Applying the boundary condition that $V = 0$ at $X = 0$

$$\frac{x}{q_0 Z} = \frac{1}{Z \sqrt{2\pi}} e^{\frac{1}{Z} \left(V_R - V + \frac{V_R^2}{2nZ} \right)} \int_{\frac{-V_R \left(1 + \frac{V_R}{nZ} \right)}{V_R / \sqrt{n}}}^{\frac{V - V_R \left(1 + \frac{V_R}{nZ} \right)}{V_R / \sqrt{n}}} e^{-\frac{1}{2} t^2} dt \quad (50)$$

After this equation the fraction of the measured retention volume that is due to "non-column effects" (19) is plotted as ordinate versus the retention volume measured in units of "effective detector volume" ($Z'/V_{R'}$)

where Z' = effective detector volume

$V_{R'}$ = retention volume corrected for dead volume of apparatus.

This gives different curves for different number of plates, that converge at low values of the detector volume parameter, $Z'/V_{R'}$ (19).

Efficiency of the Column.

Column efficiency has been measured for the height equivalent to a theoretical plate. The HETP has been defined on page -8-. The number of theoretical plates is a measure of the effective number of equilibrations which take place between the fixed and the mobile phase as the gas moves through the column.

James and Martin (17) have proposed two methods for the calculation of the number of theoretical plates from the recorded chromatograms. The first approach, considering the rate of transport of solute corresponding to the plate of maximum concentration lead them to the following equation

$$n = 2\pi \frac{h^2 L^2}{A^2} \quad (51)$$

where:

h = peak height

L = length of the chromatogram

A = area under the peak

n = number of plates.

The second alternative method of James and Martin (17) which has become the recommended ^{one}(11) for the purpose of calculating the number of theoretical plates, has its origin in the consideration that the chromatogram corresponds to

a distribution curve whose shape approaches a normal error curve. The mathematical analysis gives the following equation:

$$n = 16 \frac{L^2}{d^2} \quad (52)$$

where:

d = peak width distance between the tangents to the inflection points of the distribution curve, measured on the base line.

For a known number of theoretical plates, the HETP is given for the relation

$$H.E.T.P. = \frac{l}{n} \quad (53)$$

where:

l = length of the column.

The number of plates and the HETP consequently, have been found to be a function of the column characteristics such as length of the column, mesh size of support, ratio of stationary liquid to solid support, and^{are} also affected to a certain extent the nature of the mobile and stationary phase (20).

Application of the Theory for Determining Physical Constants.

GLPC has been used not only for analytical purposes but also to determine physical constants (3), (14), (22), (33), (35), (36) and (38). By exploiting the solution processes

taking place in the column GLPC can be used in the study of the non-ideality of solutions. The general pattern followed consists of determining typical parameters as retention volumes and partition coefficients and relating them to the properties of the systems.

For the following development it is convenient to bring out equation (29) which gives the relation of the experimentally determined parameter V_R , the retention volume, or the volume of the mobile phase passed into the column when the concentration is a maximum, as it relates to the characteristics of the column and the partition coefficient.

$$V_R^\circ = V_m + H^\circ V_s \quad (29a)$$

V_m = volume of the mobile phase in the column.

V_s = volume occupied by the stationary solvent phase in the column.

H° = partition coefficient defined as the ratio of solute per unit volume in the solvent phase to the solute per unit volume of the gas phase taken when the solute concentrations are infinitely dilute.

It must be noted that the retention volume does not depend explicitly on the number of plates in the column but depends only on the column characteristics through V_m and V_s .

In order to use equation (29a) as a basic equation to

obtain other physical and thermodynamical properties it is necessary for partition coefficients as determined to fulfill certain requirements:

a). The coefficients must be consistent if determined in columns of different characteristics and under different flow conditions.

b). They must not be influenced to an appreciable extent by the solid support.

c). They must agree essentially with those determined under well defined equilibrium conditions.

These conditions were found to be substantially fulfilled by Porter (35) who applied equation (29a) to find partition coefficients from retention volumes following the assumptions of the theoretical plate analysis of Martin (23).

Determination of K Values.

The definition of partition coefficient may be alternately expressed as:

$$H = \frac{x}{y} \frac{M_s}{M_m} \quad (54)$$

Where:

x mole fraction of solute in the liquid,

y mole fraction of solute in the gas,

M_s moles of stationary phase per cc of liquid,

M_m moles of mobile phase per cc of gas.

The agreement of the partition coefficients from GLPC with those determined under well defined equilibrium conditions, and the fact that the relation x/y appears in this equation was exploited for Rangel (36) in order to predict K values (vapor-liquid equilibria constants) for hydrocarbons in n-Decane.

Setting $\frac{x}{y} = \frac{1}{K}$

$$H = \frac{1}{K} \frac{M_s}{M_m} \quad (55)$$

The gaseous phase approaches ideal behavior, so

$$\pi V = nRT \quad \therefore \quad M_m = \frac{n}{V} = \frac{\pi}{RT} \quad (56)$$

and

$$H^{\circ} = \frac{1}{K} \frac{M_s RT}{\pi}$$

$$\text{As: } M_s = \frac{P_s}{HW_s}$$

where:

P_s = mass per unit volume of stationary phase,

MW_s = mass of one mole of stationary phase.

$$H^{\circ} = \frac{1}{K} \frac{P_s RT}{\pi MW_s} \quad (57)$$

Substituting the value of H in equation (29a) rewritten as

$$H^{\circ} = \frac{V_{R^{\circ}} - V_m}{V_s} \quad \text{gives} \quad K = \frac{P_s RT V_s}{(V_{R^{\circ}} - V_m) \pi MW_s}$$

$$\text{But } V_s = W_s / P_s$$

Then:

$$K = \frac{RT W_s}{(V_R^0 - V_m) \pi MW_s} \quad (58)$$

This equation was found (36) to give reliable K values for hydrocarbons. Its application requires a knowledge of the pressure, temperature, corrected retention volume of the solute, the volume of gas in column, weight of liquid in column, and the molecular weight of that liquid.

Determination of Solution Parameters.

For the study of non-ideal systems, solution behavior may be expressed in terms of deviations from the ideal solution. The development for the liquid phase activity coefficient, a measure of solution non-ideality, follows.

For any ideal solution of a volatile solute in a non-volatile solvent, the ideal behavior obtains in the gas phase, and:

$$\bar{p} = x p^0 \quad (59)$$

where \bar{p} = partial pressure

x = mol fraction

p^0 = vapor pressure in the pure state at the temperature of the solution.

This relation is known as Raoult's law. The liquid phase

activity coefficient is introduced into equation (59) to give

$$\bar{p} = \gamma x p^{\circ} \quad (60)$$

where \bar{p} is partial pressure exerted by an actual system; combining equation (60) with Dalton's law gives:

$$\pi y = \gamma x p^{\circ} \quad (61)$$

where

π = total pressure

γ = activity coefficient.

Rearranging (61)

$$y = \frac{\gamma x p^{\circ}}{\pi}$$

Introducing it in the expression for the partition coefficients (54)

$$H^{\circ} = \frac{x \pi}{\gamma x p^{\circ}} \frac{M_s}{M_m} \quad (62)$$

With the assumption of ideal behavior in the gaseous phase

$$\pi = M_m RT$$

where M_m = mole of mobile phase per cc of gas

$$H^{\circ} = \frac{\pi}{\gamma p^{\circ}} \frac{M_s RT}{\pi}$$

$$H^{\circ} = \frac{M_s RT}{p^{\circ} \gamma} \quad (63)$$

Equation 63 was previously derived by Porter (35).

The assumption of constant partition coefficients implies that ideal or infinite dilute solution exists over the whole length of

the column. This is consistent with the situation existing in GLPC which approaches infinite dilute solution.

The following expression can be used for obtaining activity coefficients at infinite dilution from partition coefficients:

$$\gamma^{\circ} = \frac{M_s RT}{H^{\circ} p^{\circ}} \quad (64)$$

This relation which contains a solute dependent factor (p°), a solvent dependent factor (M_s), and a solute solvent dependent factor (γ), has proven useful in the study of solute solvent effects (3), (33), (35) and (36). The expression for the activity coefficients can be set in terms of the directly measured corrected retention volume

$$V_R = V_m + HV_s \quad (29a)$$

Substituting H° from (63)

$$V_R^{\circ} = V_m + \frac{M_s RT}{\gamma^{\circ} p^{\circ}} V_s$$

and therefore

$$\gamma^{\circ} = \frac{M_s RT V_s}{(V_R^{\circ} - V_m) p^{\circ}} \quad (65)$$

The activity coefficient, together with the data for the pure substances can be exploited in many useful ways. Through the application of the activity coefficients established by Equation 65, GLPC can be used to:

1. - Study extractive distillation systems.
2. - Evaluate thermodynamic data.

Application of GLPC to Study Extractive Distillation Systems.

In extractive distillation, a substance not normally presented in the mixture and relatively non-volatile is added in order to increase the difference in volatilities of the most difficultly separable components.

The most convenient measure of the difficulty of separation of two liquids is the relative volatility or relative distribution ratio, defined as the ratio of the compositions of the components in one phase to the ratio of the compositions in the other phase. For a vapor-liquid system:

$$\alpha_{1,2} = \frac{\frac{y_1}{y_2}}{\frac{x_1}{x_2}} \quad (66)$$

where y_1 and y_2 are the mole fractions of the two components in the vapor, and x_1 and x_2 are the mole fractions of the two components in the liquid.

Writing equation 61 for components 1 and 2,

$$\begin{aligned} y_1 \pi &= \gamma_1 x_1 p_1^\circ \\ y_2 \pi &= \gamma_2 x_2 p_2^\circ \end{aligned} \quad (61a)$$

introducing the resulting expressions in Equation 66

$$\alpha_{1,2} = \frac{\frac{\frac{\gamma_1 x_1 p_1^\circ}{\pi}}{\frac{\gamma_2 x_2 p_2^\circ}{\pi}}}{\frac{x_1}{x_2}} = \frac{\gamma_1 p_1^\circ}{\gamma_2 p_2^\circ} \quad (67)$$

At high pressures, the vapor pressures are replaced by fugacities. α is a constant for a given temperature. The relation γ_1/γ_2 can be varied by addition of a third component to the binary system; this component (solvent) forms non-ideal solution with one or both of the components and exaggerates the difference in volatility between them. This addition is only effective when the extractive agent appears in large quantities in the liquid phase.

GLPC may be exploited to study extractive distillation because the stationary liquid (solvent) usually has a much higher boiling point than the components of the mixture to be separated, and is presented in comparatively large amount. This fact has been pointed out by Herrington (14) and Rock (38). The resulting relative volatilities at infinite dilution will be indicative of the separation to be achieved by extractive distillation.

Calculation of Thermodynamic Data:

The retention volumes, partition coefficients, or the activity coefficients can be related to other thermodynamic properties connected with the behavior of solutions. In fact this data should be presented as a support of the soundness of those parameters determined from GLPC.

Heats of Solution.

Heats of solution have been calculated from chromatographic

data (3), (22), and (35). Littlewood (22) used the corrected retention volume that is related to the temperature for one expression of the Clausius-Clapeyron type

$$\frac{d \ln V_R^\circ}{dT} = \frac{\Delta H_{sln.}}{RT^2} + K \quad (68)$$

K includes terms such as the temperature coefficient of expansion of the phases and $\Delta H_{sln.}$ = differential heat of solution.

Heats of solution may also be obtained from the partition coefficients. Writing Equation 63 in logarithmic form:

$$\ln H^\circ = \ln M_s RT - \ln \gamma^\circ - \ln \rho^\circ \quad (63a)$$

Considering the variation with temperature Equation 63a becomes:

$$\ln H^\circ = \ln M_s R - \ln \frac{1}{T} - \frac{\Delta H_s^E}{RT} + \frac{\Delta H_v}{RT} + K \quad (69)$$

where: ΔH_s^E is the excess partial heat of solution of the solute in the solvent

ΔH_v is the heat of vaporization of the solute.

Since the molecular volume of the solvent is normally not very dependent on temperature, its variation can be neglected.

$$\frac{\partial \ln H^\circ}{\partial \frac{1}{T}} = -T - \frac{\Delta H_s^E}{R} + \frac{\Delta H_v}{R} = \frac{\Delta H_v - RT - \Delta H_s^E}{R} \quad (70)$$

The plot of logarithm of partition coefficient versus $1/T$ gives a linear relation which permits the evaluation of ΔH_s^E .

This way was followed by Porter (35) in order to obtain data of heats of solution.

The heat of solution can be obtained from the variation of activity coefficients with temperature. The activity coefficient can be defined as

$$\gamma_i = \frac{a_i}{N_i} = \frac{f_i}{f_i^\circ N_i} \quad (71)$$

Then

$$\left(\frac{\partial \ln \gamma_i}{\partial T} \right)_P = \left(\frac{\partial \ln f_i}{\partial T} \right)_P - \left(\frac{\partial \ln f_i^\circ}{\partial T} \right)_P \quad (72)$$

As

$$\left(\frac{\partial \ln f}{\partial T} \right)_P = \frac{H_i^* - \bar{H}_i}{RT^2} \quad (73)$$

Therefore

$$\left(\frac{\partial \ln \gamma_i}{\partial T} \right)_P = \frac{(H_i^* - \bar{H}_i) - (H_i^* - \bar{H}_i^\circ)}{RT^2} = \frac{(\bar{H}_i - H_i^\circ)}{RT^2} \quad (74)$$

This can be written as

$$\frac{d \ln \gamma_i}{d \left(\frac{1}{T} \right)} = \frac{\Delta H_{sln.}}{2.303 R} \quad (75)$$

Where $\Delta H_{sln.}$ = differential heat of solution, BTU/lb. mole

T = temperature absolute °R

R = gas constant, 1.987 BTU/lb. mole °R

The term of the left-hand side of the equation is the slope of the curve when $\log \gamma$ for a hydrocarbon is plotted against $1/T$. At infinite dilution $\log \gamma^\circ$ is numerically equal to the Margules binary constant, A_1 . As in certain limits A_1 is a straight line function of $1/T$, the heats of solution are easily obtained from the relation.

Carlson and Colburn (7) observe that in general if the activity coefficient of a system is less than one the heat of solution is positive, and if larger than one the heat of solution is negative. In either case, an increment of temperature causes the activity coefficients to approach zero.

Some other useful data can be obtained from at infinite dilution. Thus the partial molal excess free energy is obtained (16) from the equation

$$\bar{G}^E = RT \ln \gamma^\circ \quad (76)$$

The partial molal excess of entropy can be obtained applying the general relation

$$G = H - TS \quad (77)$$

That gives

$$\begin{aligned} \bar{G}^E &= \bar{H}^E - T\bar{S}^E \\ \bar{S}^E &= \frac{\bar{H}^E - \bar{G}^E}{T} \end{aligned} \quad (78)$$

Finally, the Van Laar constant A_1 is related to the activity coefficient at infinite dilution for $A_1 = \log \gamma_{1,2}^\circ$

$$(79)$$

EXPERIMENTAL

APPARATUS

The apparatus built for this study is shown in Figs. 1 and 2. Fig. 3 is a schematic diagram of the apparatus. It can be described^{by} following the gas stream.

The carrier gas contained in a storage cylinder is supplied at constant pressure through a diaphragm regulator (Hoke-Phoenix) into two coils: a preheater coil, and a coiled column packed with a granular solid which has been properly impregnated with a suitable high boiling liquid. The latter constitutes the chromatographic column.

A sampling system is connected by means of a by-pass arrangement to the carrier gas stream. When the by-pass valve is closed the gas stream is divided into two parts. One stream goes directly through the preheated coil branch while the other pushes the sample from the by-pass through the chromatographic column. These two streams flow through the reference and sample passage of a thermal conductivity cell (katharometer), and respectively, leave the apparatus through different flowmeters. The flow rates are controlled by needle valves located on the downstream side of the katharometer.

FIG 1.- ASSEMBLED APPARATUS.

FIG 2.-CONTROL PANEL.

The katharometer, which consists of a Wheatstone bridge with a branch for reference and the other for sample corresponding to the two flow passages, was previously adjusted with carrier gas passing through both sides in such a manner that its output record in a self-balancing potentiometer traces a zero signal. When the by-pass valve is closed the gas sample is displaced with the carrier gas which pushes it through the chromatographic column. When the sample reaches the katharometer, it determines an unbalancing of the Wheatstone bridge which is recorded by the potentiometer over a period of time as a peak.

The apparatus described was designed specifically for use in obtaining physical chemical data from the experimental retention volumes. Some features of the apparatus will be mentioned in the following paragraphs.

Sample System. Sample size and charging technique affect the position and shape of the peaks in a chromatogram.

Theory prescribes that the sample must be initially contained in the first plate. That is, the charge must be made as small as possible to avoid the formation of an initial band which overspreads a significant length of column.

FIG. 3 - SCHEMATIC DIAGRAM OF APPARATUS .

Partition coefficients must be measured at very low concentrations or with small sample volumes in order to approach the infinitely dilute region where the coefficients are constants, i. e. the ratio of concentrations in the two phases is constant.

In the charging technique two cases can be differentiated: plug flow and exponential mixing. In the first case the chromatogram is symmetrical, while the second case is not. The first case represents a better condition for the estimation of the retention volume than the second case when the solute concentration falls to zero exponentially.

The sample system of 1 ml. of gas capacity was made with the chamber connected to two 3-way stopcocks as shown in Figure (3). The sample container was provided with a pressure regulator and a valve for make the samples reproducible. When the valves are correctly operated, the introduction of the sample into the column approaches plug flow.

Columns. Columns were made of 3/8 in. copper tubing, which were coiled after packing. The length was selected to give a low pressure drop while giving retention times long enough for accurate reading.

Dead Volume. In an ideal chromatographic unit there would be

no dead volume between the sample system and the column and no dead volume between the latter and the detector. In the apparatus the dead volume was minimized by using capillary copper tubing whenever possible. The total volume was thereby reduced to 3 ml. before the column and 2.1 ml. after it.

Detector. Some desirable characteristics of detectors are: rapid response, good stability, high sensitivity, low dead volume, linear response with concentration, and relative insensitivity to changes in flow and pressure.

A Pretzell cell T/C 9285 manufactured by the Gow-Mac Instrument Co., Madison, N.J., with 8 filaments incorporates these features to an acceptable degree. The gas volume of the cell is relatively small (4.655 ml.). The cell block design is so that the filaments are on stream giving a time constant practically limited to the pen speed of the recorder. This design, however, increases the sensitivity of such cells to changes in flow which may be overcome by providing a well-regulated flow system. The schematic wiring diagram is given in Fig. 4.

Constant Temperature Bath. The bath consists of a 5-gallon Dewar flask supported in a metal box. The bath is attached to a lifting system. While in upper position, it encloses the

FIG. 4 - SCHEMATIC WIRING DIAGRAM FOR KATHAROMETER.

column, reference coil, katharometer, etc.

The compactness of the column leaves enough room for bath heaters, stirrer and a thermo-regulator. The heating devices are a quick heat unit of 300 watts normal power rating and a 100 watts connected to a Fenwall bimetallic thermo-regulator, for maintaining temperature constant within 0.05°C. Heaters are connected through Powerstats whose position is manually adjusted according to the demands.

Water and ethyl alcohol were used as bath fluids, and ice, dry ice and the heaters were used to obtain the desired temperature.

Flow Control and Measurement. The rate of flow is controlled by the pressure at the head of the column, the pressure drop through it; and[†] is governed by two needle valves located just after the katharometer, one in the reference stream and the other in the sample stream.

The pressure of the carrier gas was regulated by a Hoke-Phoenix diaphragm regulator. The pressure drop through the column was measured by a differential manometer 0 to 100 in. water (Industrial Instrument Corporation, Odessa, Texas), and the pressure in the column outlet by a test gauge (Jas. P. Marsh Corp., Chicago, Ill.). The flow in the reference side was measured with a flowrator 3 to 170 ml. /min.

range (Fisher & Porter), and the flow in the sample side with a calibrated Burrel Flowmeter Mod. 840-70 with range from 0 to 100 ml/min.

Materials.

Methane - Tennessee Gas Transmission Company - 99.6% purity

Ethylene - The Houston Oxygen Co.

Ethane - Phillips Petroleum Co. Research grade - 99.9% "

n-Propane - Phillips Petroleum Co. Instrument
grade - 99.5% "

n-Butane - Phillips Petroleum Co. Instrument
grade - 99.5% "

Butene-1, cis-Butene-2, trans-Butene-2,

Butadiene 1-3 - Phillips Petroleum Co. pure grade - 99% min. "

n-Dodecane - Matheson Coleman Co., Inc. - 95% "

Isopentane - Phillips Petroleum Co. Technical grade 95% "

Furfuraldehyde - Petro-Tex Chemical Corp. - 99.81% "

Solid Support - Crushed diatomaceous earth
firebrick, Curtin C-3.

Preparation of the Column. In order to insure an even distribu-

tion of the stationary liquid phase over the surface of the solid, the stationary liquids, n-dodecane in one case and furfural in another were dissolved in 8 to 10 times their volumes of a low boiling solvent, isopentane and ethyl ether respectively.

TABLE 1

Column Characteristics*

	Length (cm)	Ratio Support/ Solvent	Column Volume (cc)	Support Volume (cc)	Liquid Volume (cc)	"Free" Gas Volume (cc)	Mass Station- ary Phase (gr)	Free Gas Cross Section (cm ²)	Free Liquid Cross Section (cm ²)	Mesh Size

*All of them were built with copper tubing 3/8"OD and 0.305"ID.

The solid support which was carefully sized and thoroughly dried, is added to this solution at the rate of 100g. of solid for 20 to 30g of stationary liquid to make a loose slurry with it. The low boiling material is slowly evaporated with mild stirring on a steam bath to avoid loss of the solute. The final traces of volatile liquid are eliminated by drying the packing material overnight in an oven at constant temperature (approximately 100°C).

In each step of this preparation quantities of material are weighed carefully. After drying the solid is weighed again in order to know the exact pick-up of stationary phase. The total column volume was determined by filling the empty column with a known volume of liquid.

For filling the column, it is maintained in vertical position, and a glass wool plug is inserted in the bottom. The packing material is added while the column is tapped with a heavy wall hose. This is continued until no further setting of material takes place. Then the upper end is covered with a glass wool plug and the column coiled in 5" diameter coil.

The gas space was estimated from the difference between the total column volume and the volume of the solid and liquid phases. The uncertainties of this method of estimation have been discussed (3). Realizing the importance of these values for the

ultimate accuracy of the thermodynamic data, the determinations were made carefully.

Life of the Chromatographic Columns. The chromatographic columns have a finite life, but the useful life depends on the nature of the stationary phase and the manner in which they are used. Columns of n-dodecane, which has very low pressure at the temperature involved, can be used for a large number of runs without showing any deterioration. This deterioration would show in the form of shorter elution times, but this did not occur in the columns after 100 runs in some cases.

The furfural columns, considering the higher vapor pressure, were used for a small number of runs (15 - 20 each one). After that number of runs none show any deterioration.

Operation of the Apparatus. With the bath adjusted at the desired temperature, helium was passed at flow rates of 50 to 70 ml./min. through the preheater coil and the chromatographic column. This flow was obtained with inlet pressures ranging from 19 to 40 psia. The two streams were passed through the katharometer and the flow regulated by the needle valves. The current to the katharometer was maintained constant and the potentiometers attached to the recorder adjusted under stabilized conditions to zero output. The sampling

system is evacuated and the sample introduced to a reproducible pressure slightly in excess of the atmospheric pressure. The sample is trapped between the two three-way valves and the lead lines evacuated.

At this point the by-pass valve is closed and the valving system manipulated so as to displace the sample into the column. A stop watch was used to measure the elution time.

Apparent retention volumes are then estimated from the time of sample introduction, the time of efflux of the maximum peak and the flow rate corrected to the operating conditions. This value of the retention volume will be subsequently corrected for dead volume in ^{the} apparatus and detector, sample size, pressure drop through the column and will be called corrected retention volume. This parameter will be the basis for the calculation of physical constants.

RESULTS

In order to apply the equation which relates chromatographic parameters to physical chemical constants, the retention volumes were calculated as the product of the rate of flow times the period elapsed from the injection point to the maximum of the distribution curve, which corresponds to the maximum concentration in the effluent. These retention volumes were corrected for pressure drop (Equation 41), for the dead volume of the apparatus, for the dead volume of detector using the plot obtained for Johnson and Stross (19) and for the volume of sample (Equation 45). The values obtained were called "corrected retention volumes" and are tabulated in Tables 2 to 6 and Appendix A and B.

Different analyses were conducted on the corrected retention volumes obtained for the system of light hydrocarbons in $n\text{-C}_{12}$ and for the system of C_4 hydrocarbons in furfural. In the first case Equation 65 was applied in order to get information of vapor liquid equilibria ratios (K values). The results are presented in the Tables 2 to 6 and Appendix A and in Figs. 9 to 16. They show in each case, the K values obtained experimentally as a function of pressure and temperature compared with those values reported for similar conditions in the Natural Gasoline Association of America (NAAA) charts. The agreement of the values obtained in this work and the NAAA values was excellent for n-butane but increased in disagreement with decrease in molecular size. The observation of a gradual agreement with

the increase of molecular weight yielded the plot showed in Fig. 17.

The corrected retention volumes obtained for the systems of C_4 hydrocarbons in furfural were directed to the determination of other solution parameters. For this purpose the corrected retention volumes were introduced into Equation 63 and the partition coefficients were obtained. These values are given in Table Appendix B. The partition coefficients were the basis for the calculation of activity coefficients at infinite dilution from Equation 65 and are presented in Table 7 and in Fig. 18. The only data available for comparison is the work of Hertea and Colburn (28), which was carried out at higher temperatures. The observation of the approximate linearity of the log of activity coefficient at infinite dilution versus the reciprocal of the absolute temperature was exploited here to extrapolate the experimental values. The agreement of the activity coefficients obtained from the two sources are demonstrated in Fig. 18. The vapor pressures employed for the calculation of the activity coefficients are presented in the Appendix D.

The consistency of the activity coefficients obtained permitted the evaluation of some other thermodynamic properties: heat of solution, excess free energy of solution, excess entropy of solution, relative volatilities, and Van Laar constants. These results are given in Tables 8 to 11.

Values of heat of vaporization are reported with the values of heat of solution for convenience in estimating the net heat

effect when the hydrocarbons in vapor phase dissolve in furfural in which case the net heat evolved would be the difference between latent heat and heat absorbed on mixing.

Discussion.

The non-linearity of the distribution isotherms is related to the variations of the activity coefficients. An isotherm is linear when Raoult's or Henry's Law applies, in which case

$\gamma = 1.0$ or $\gamma = \text{a constant}$ respectively. Should the activity coefficients be a function of concentration, it follows that parameters related to it may also be expected to vary with concentration.

The departure from linearity may assume the shape shown in Figure 5, b and c. In the case presented in Figure 5b,

k' is smaller and H greater in the more concentrated region. The higher concentration region runs with smaller velocity than the small concentration portion, resulting in a steep drop in the concentration profile and a broad profile in the leading portion of the curve. The reverse consideration is valid for the case of Figure 5c, where k' is larger and the partition coefficient smaller in the more concentrated region. The slower movement of the lower concentration part of the band causes a steepening of the band front. These effects are more appreciable at the beginning of the column. For longer columns the effect vanishes. These cases are presented in Figure 5 which shows that the measurement of the registered curve becomes difficult and the determination of t_{max} is not accurate.

FIG. 5 - SHAPE OF THE ISOTHERMS & CONCENTRATION PROFILE.

In the determinations performed here, however, the columns were long and the concentration was low enough for the isotherms to fall in the linear region, yielding a symmetrical profile in the chromatogram. The cases in which the concentration-time curves registered slight asymmetry were attributed to low flow rates where the diffusion effects can be significant. Asymmetric elution curves will also result if sufficient stationary phase is not placed on the solid leaving sites of varying activity.

Flow Rate. - For the range of flow rate treated, 30 to 70 ml/min., corresponding to a linear velocity from 1.4 to 2.5 cu./sec., the retention volumes were found substantially independent of the flow rate.

Fig. 7 shows the variation of the HETP with the flow rate. It shows the normal trend of those reported in the literature (20) and (40), a curve with a flat minimum, which corresponds to the best working conditions. That flat minimum corresponds to flow velocities for which the resistance to mass transfer is very low. K -values determined from the retention volumes corresponding to the points shown in Figure 7 do not exhibit consistent variation with HETP. Apparently the velocities reached were not low enough to introduce longitudinal diffusion in the gas phase to a significant extent.

Solid Support. Throughout the experiments only one type of support, a granulated firebrick, Curtin C-3, was used. When coated with stationary liquid it did not tend to form clusters, thus permitting the construction of a uniformly packed column.

FIGURE No. 6 .

**FIG. 7.- VARIATION OF H.E.T.P. WITH THE LINEAR
 VELOCITY OF THE GAS.**

Two different sizes of packing were used 30 to 50 and 48 to 60 mesh. A given solute was eluted through columns with different size of packing. Figure 6, where the log of the partition coefficients are plotted versus the reciprocal of the absolute temperature, shows the linear relationship previously demonstrated (35), even though the runs were made with columns of different packing size.

The non influence of diameter size in a certain range can be attributed to the porous nature of the solid with a large specific area where no critical contribution is given for the increase of external area, occasioned by the reduction of particle size. Some authors (21) remark that a more coarse material permits a more regular column packing than a fine that is more liable to lead to channeling and would also occasion a significant pressure drop through the column.

Sample Volume.

The correction to the retention volume for sample volume was shown through the use of Equation 45 (40) to be negligible.

The linear relation of the logarithm of the partition coefficients of the members of an homologous series, as observed for Littlewood (22) was applied successfully to the values obtained in this investigation for ethane through butane and did not hold for methane, Fig. 8.

Vapor liquid equilibrium constants were obtained from the retention volumes. The results are presented in the usual form is isotherms in Figures 9 to 16.

FIG. 8.—CORRELATION OF THE PARTITION COEFFICIENTS OF THE LIGHT HYDROCARBONS.

The values plotted represent averages of several runs at different rates. The NIAA (29) values given for the K in the same conditions are also plotted for comparison. The values determined show a gradual agreement with static values as a function of the molecular size with the methane showing the largest disagreement. The trend of the agreement is presented in Fig. 17 at different temperatures and pressures. From this plot it is observed that better agreement appears at the lower temperatures and pressures.

In the restricted range of temperature, isobaric K values appear almost linear, same as the static determined K values. This characteristic holds better for n Butane and decrease to methane. The K values obtained by chromatographic technique show a definite influence of pressure. Values obtained at pressures near the atmospheric agree with those determined by static methods, but increasing the pressure the chromatographic values are high.

The values of the activity coefficients at infinite dilution for the system of C_2 -hydrocarbons in furfural, obtained in this experimental work are presented in Table 7. In Fig. 18 the coefficients are plotted against the reciprocal of the absolute temperature, together with the data obtained by Hertel and Colburn (28). The data of Colburn comes from the extrapolation to zero concentration of a series of values obtained at different concentrations. The experimental values are consistent with those predicted from the data of Hertel and Colburn (28).

FIG.14-COMPARISON OF CHROMATOGRAPHIC K VALUES WITH THE N.G.A.A. VALUES— CONSTANT PRESSURE.

For this reason it is felt that good values of the differential heats of solution could be obtained from the variation of the activity coefficients, with temperature. The calculated differential heat of solution for normal-butane from these studies was 3900 BTU/lb. mole from 20 to 40°C., while Martens and Colburn's value was 3150 BTU/lb. mole when evaluated from 35° to 93°C. For 1-butene in furfural the value obtained by chromatographic technique was 2565 BTU/lb. mole while the results from Reference (28) showed a value of 2400 BTU/lb.mole.

The relative volatilities calculated through the equation presented in Table 9 are reasonably close to the values from the literature (6) reproduced in the same Table 9.

It was interesting to notice the separation of cis- and trans-butene through the chromatographic technique. The values of the partition coefficients were far enough apart to insure a good separation. This suggests the use of chromatography in the separation of stereoisomers. Some work is reported in diphenyl-polyenes and azobenzene (42) but an explanation of the dependence of absorption and spatial configuration is not available. In this simple case, however, it is reasonable to explain the difference in partition coefficients on the basis that for two substances whose boiling points are nearly equal, the more polar or more easily polarized substance will have the greater solubility in a polar liquid such as furfural. According to the geometrical picture

adopted in organic chemistry.

CIS-BUTENE-2

TRANS-BUTENE-2.

the trans form presents the higher degree of symmetry. Therefore, the cis-form would be expected to be more easily polarized in the presence of furfural and is consequently retarded by virtue of its increased solubility.

Butadiene, 1-3	.663	.625	.615	.583

C O N C L U S I O N S

1. The Application of the chromatographic technique to obtain vapor-liquid equilibria ratios (K values) gave results which are in "gradual agreement" with those reported from smoothed values of experiments carried under static equilibrium conditions. This agreement ranges from close values for butane to considerable disagreement for methane. The effect of pressure was noticeable. Values obtained at pressures close to the atmospheric pressure were in good agreement but values at higher pressures were found higher than those reported from static methods.

2. The influence of different factors such as flow rate, temperature, etc. upon the experimental parameters in GLPC was found to agree with previous conclusions.

3. The thermodynamic data related to solution behavior in the form of activity coefficients for the C₄-hydrocarbon system through chromatographic methods was in general agreement with available static results.

4. A practical application is visualized for the GLPC as a means of selecting extractive agents in extractive distillation. The resulting activity coefficients will not only provide the values of the volatilities but will also give information on heat effects so valuable in the design of the towers. The simplicity and speed of the method enable the testing of many possible agents in a minimum of time.

NOMENCLATURE

A = feed volume, (c. c.)

a = gas cross section of column, (cm²)

A₁ = Van Laar Constant.

A = area of chromatogram, (cm²)

A, B, C = Constants in Antoine's equation.

c, c'' = integration constants.

C = concentration, (suitable unit/c. c.)

C₀ = concentration of solute in the feed, (suitable unit/c. c.)

d = peak width, (cm)

e = base of natural logarithms, 2.7183.

F = rate of flow at outlet conditions, (c. c./sec)

f = fugacity

\overline{G}^e = partial molar excess free energy, (BTU/lb. mole)

GLPC = Gas Liquid Partition Chromatography.

H = partition coefficient = $\frac{C_s}{C_m}$ at equilibrium.

h = peak height of the chromatogram, (cm)

H. E. T. P. = height equivalent to a theoretical plate.

H_{sln} = differential heat of solution

K = $\frac{y}{x}$ = vapor-liquid equilibrium constant.

K = constant

L = length of the chromatogram. Distance from the injection point to the maximum of the distribution curve, (cm)

l = column length, (cm)

M = total volume of mobile phase flowed through the column, (c.c.)

M = moles of one phase per c.c.

MW = molecular mass

m = width of the elution curve

n = number of plates in the column

n = number of moles.

p = pressure at any point of the column, (psia).

p_1 = pressure of gas applied to chromatographic unit, (psia)

p_0 = outlet pressure, (psia).

\bar{p} = partial pressure, (psia)

q_0 = amount of material charged to the first plate.

R = gas constant

R_f = retardation factor ratio of traveling velocities of the solute and the solvent.

S^e = partial molal excess entropy

t = elution time, (sec)

T = absolute temperature, ($^{\circ}K$ or $^{\circ}R$)

u = linear velocity of gas, (cm/sec)

V = volume of one phase in the column, (c.c.)

V_0 = volume of the solid support in column, (c.c.)

v = volume of one phase in one plate, (c. c.)

v = effective plate volume, (c. c.)

V_R = retention volume. Volume of the mobile phase passed through the column when the concentration in the effluent is a maximum, (c. c.)

V'_R = retention volume corrected for dead volume of apparatus, (c. c.)

V°_R = corrected retention volume, (c. c.)

x = amount of sample in detector chamber

x = mole fraction. Mole fraction of solute in the liquid phase.

y = mole fraction of solute in the gas phase.

Z = detector volume (c. c.)

Z' = effective detector volume. Detector volume estimated from the descending portion of the distribution curve, (cc)

Greek Letters.

$\alpha_{1,2}$ = relative volatility of components 1 and 2.

γ = activity coefficient

π = total pressure, (psia)

ρ = density (gr/c. c.)

Subscripts.

m = refers to the mobile phase.

s = refers to the stationary phase.

Superscripts.

^o = to indicate reference state or corrected value

* = to indicate ideal state.

Note: The Roman numbers before the serial number of any experiment, corresponds to the column in Table 1.

Sample Calculations

For the run V-388* from the data in the Appendix B

$$T = 273.2 \text{ } ^\circ\text{K}$$

$$F = 60 \text{ cc/min}$$

$$P_1 = 29.2 \text{ psia}$$

$$P_0 = 28.2 \text{ psia}$$

$$t = 297 \text{ sec.}$$

$$\text{mean pressure in the column } \bar{P} = \frac{29.2 + 28.8}{2} = 29 \text{ psia}$$

Calculation of corrected flow rate. The orifice flowmeter gives the flow rate at 1 atm and 9°C and it must be corrected to the actual working conditions.

For the conditions before the column

$$F = \frac{60}{60} \times \frac{14.7}{29.2} \times \frac{273.2}{282.2} = .486 \text{ cc/sec}$$

For the conditions at the end of the column.

$$F = \frac{60}{60} \times \frac{14.7}{28.8} \times \frac{273.2}{282.2} = .494 \text{ cc/sec}$$

$$\text{Uncorrected retention volume} = 297 \text{ sec.} \times .494 = 146.5 \text{ cc.}$$

Correction Factors.

a). For pressure drop

$$\frac{P_1}{P_0} = \frac{29.2}{28.8} = 1.014$$

Applying Equation

$$\frac{V_R}{V_{R^0}} = \frac{2}{3} = \frac{1.014^3 - 1}{1.0142 - 1} = 1.007$$

b). For dead volume of apparatus

$$\text{Before the column} = \frac{3 \text{ cc}}{.486 \text{ cc/seg}} = 6.17 \text{ sec.}$$

$$\text{After the column} = \frac{2.1}{.494} = 4.25 \text{ sec.}$$

$$\text{Total} = 10.42 \text{ sec.}$$

expressed in volume:

$$10.42 \text{ sec.} \times .494 \frac{\text{c.c.}}{\text{sec}} = 5.15 \text{ c.c.}$$

c). For Sample Size.

The number of plates is given by Equation (52)

$$n = \left(4 \frac{L}{d} \right)^2$$

from chromatogram

$$L = 12.57 \text{ cm.}$$

$$d = 2.74 \text{ cm.}$$

$$n = \left(4 \times \frac{12.57}{2.74} \right)^2 = (18.367)^2 = 337 \text{ plates.}$$

Applying Van Deemter Equation

$$\frac{.5 \times 146.5}{18.367} = 3.99$$

As $3.99 > 1$ cc (sample size volume, no correction for sample

size is necessary

d). Correction for Detector Volume.

From the Chromatogram.

$$Z' = 1.865 \text{ cm.}$$

$$V_R' = 146.5 - 5.15 \text{ cc.} = 141.35$$

$$Z'/V_R' = .0132$$

In fig. 5 Ref. 19

Z'/V_R' falls in an approximate 45° line versus the parameter retention volume due to detector/retention volume. Then retention volume due to detector = $.0132 \times 141.35 = 1.86 \text{ cc}$
 Summary of corrections.

Uncorrected retention volume = 146.50 cc.

- correction for dead volume = 5.15 cc

- correction for detector volume = 1.86 cc = 139.49 c.c.

For pressure drop

$$V_{R^0} = \frac{139.49}{1.007} = \underline{\underline{138.1 \text{ c.c.}}}$$

V_{R^0} = corrected retention volume = 138.10 c.c.

Alternative I. - Determination of K values

$$V_m = 38.3$$

$$V_{R^0} - V_m = 138.10 - 38.30 = 99.80 \text{ c.c.}$$

Introducing in Equation 58

$$K = \frac{84780 \times 273.2 \times 7.3916}{96.08 \times 29 \times 70.3 \times 99.80} = 8.26$$

Alternative II. - Determination of Activity Coefficients

From equation 29a

$$H^{\circ} = \frac{V_{R^{\circ}} - V_m}{V_s} = \frac{99.80}{6.37} = 15.68$$

Substituting in Equation 64

$$V = \frac{M RT}{H^{\circ} P^{\circ}} = \frac{.01207 \times 62361 \times 273.2}{15.68 \times 774.52} = 11.89$$

Note: The K value obtained shows the calculation method only. It is necessary to pointed out that it was obtained using furfural as liquid phase. For this reason it is not expected to check with the conventional K values.

VAPOR PRESSURES OF C₄ HYDROCARBONS

Calculated from Antoine's Equation

	<u>Antoine's Equation Constants</u>				<u>Vapor pressures in mm. Hg</u>			
	A	B	C		-20°C	0°C	20°C	40°C
